Keywords: galactinol, periplasmic binding protein, RFOs, plant defence, *Agrobacterium fabrum*

ABSTRACT

The bacterial plant pathogen *Agrobacterium fabrum* uses periplasmic binding proteins (PBPs) along with ABC transporters to import a wide variety of plant molecules as nutrients. Nonetheless, how *A. fabrum* acquires plant metabolites is incompletely understood. Using genetic approaches and affinity measurements, we identified here the PBP MelB and its transporter as being responsible for the uptake of the raffinose family of oligosaccharides (RFOs), which are the most widespread D-galactose containing oligosaccharides in higher plants. We also found that the RFO precursor galactinol, recently described as a plant defense molecule, is imported into *Agrobacterium* via MelB with nanomolar range affinity. Structural analyses and binding mode comparisons of the X-ray structures of MelB in complex with raffinose, stachyose, galactinol, galactose and melibiose (a raffinose degradation product) revealed how MelB recognizes the nonreducing end galactose common to all these ligands and that MelB has a strong preference for a two-unit sugar ligand. Of note, MelB conferred a competitive advantage to *A. fabrum* in colonizing the rhizosphere of tomato plants. Our integrative work highlights the structural and functional characteristics of melibiose and galactinol assimilation by *A. fabrum*, leading to a competitive advantage for these bacteria in the rhizosphere. We propose that the PBP MelB, which is highly conserved among both symbionts and pathogens from *Rhizobiace* family, is a major trait in these bacteria required for early steps of plant colonization.

The plant-rhizospheric microbial population interaction is dynamic and largely influenced by roots exudates, with either beneficial or harmful consequences for plant growth development and health (1). The germinating seeds in contact with the surrounding soil and microorganisms have strong influences on the rhizosphere composition and favour fast growing microorganisms able to exploit carbon released, to resist to antimicrobial compounds, and to outcompete other surrounding bacteria (2–4). Raffinose and stachyose from the Raffinose Family of Oligosaccharides (RFOs) accumulate in plant seeds as energy storage metabolites, and are released during plant germination (2, 5). The precursor of RFOs synthesis namely galactinol, a D-galactose bound to an inositol, is produced by the plant enzyme Galactinol synthase (5, 6) (GolS) (Fig. 1). Galactinol plays an important role in plant health, being involved in plant resistance against abiotic (drought and temperature (7, 8)) and biotic stresses (9–11). Indeed, this molecule, which accumulates in plant in response to bacterial inoculation, is involved in the induced systemic resistance to phytopathogens (9). Raffinose and stachyose are synthesized from sucrose by the subsequent addition of activated galactose moieties donated by galactinol using plant raffinose and stachyose synthases, respectively (Fig. 1). Therefore, RFOs are α-1,6-galactosyl extensions of sucrose.

Periplamic Binding Proteins (PBPs) associated with their ATP-binding cassette ABC transporter

are essential for transport (12). A PBP-mediated transport system is responsible for RFOs uptake from seed exudates into bacterial cells as previously shown in *Ensifer meliloti* 1021 (13, 14). RFOs, which are degraded by α-galactosidases in this latter strain, are used as nutrients and their assimilation may be involved in bacterial survival in plant rhizosphere (13, 14). In more detail, raffinose and stachyose can be degraded into melibiose and fructose, and raffinose and galactose, respectively (15, 16). Bacterial assimilation of RFOs and melibiose was associated to trophic advantage in plant-bacteria interaction (14, 17), while nothing was known for galactinol.

Agrobacteria are telluric and rhizosphere bacteria commonly isolated from roots of numerous plants as commensal bacteria. They can also be pathogenic with the presence of the Tumor inducing plasmid (18, 19). They are then able to create their own ecological niche after plant cell transformation that leads to tumor formation in a wide range of plants (18). An *in silico* analysis of α-galactosidases distribution in bacteria indicated that *Agrobacterium fabrum* C58 strain contains an operon putatively involved in RFOs transport and degradation (20–22). This operon that we named *mel* is similar to the *agp* operon of *E. meliloti* (13, 14), and encodes the PBP MelB (Atu4661) which shares 73% sequence identity with the PBP AgpA, its associated ABC transporter (Atu4662-Atu4664) and two α-galactosidases (Atu4660 and Atu4665). All these latter proteins display between 74% and 86% sequence identity with their *E. meliloti* corresponding homologues (Fig. 2a).

We hypothesized that this *mel* operon was responsible for the transport and assimilation of α-galactosides in *A. fabrum*. Here, we focused on its transport function, and investigated the genetic and molecular role of the PBP MelB through an integrative approach using a defective mutant *in cellulo* and *in planta*, crystallography and affinity measurements. We showed that MelB was the PBP responsible for RFOs, melibiose and galactinol import into *A. fabrum* C58, displaying the highest affinity for galactinol in nanomolar range and preferring to bind a 2 units-ligand. We structurally characterized the binding mode of MelB for its different ligands. Overall, our work highlights how the capacity of agrobacteria to assimilate plant α-galactosides confers them an advantage in colonizing efficiently the plant tomato rhizosphere, explaining why the PBP MelB is highly conserved among symbionts and pathogens rhizobiales.

RESULTS

The PBP MelB is responsible for galactinol, melibiose and RFOs (raffinose and stachyose) uptake. The growth profiles of *A. fabrum* C58 wild type (WT) and C58Δ*melB* defective mutant for MelB were compared in rich (YPG) and minimal medium containing RFOs, their derivatives or succinate (as control) as the sole source of carbon. The C58Δ*melB* mutant has the same growth rate as the WT strain in minimum medium with succinate and in rich medium. However, the C58Δ*melB* mutant did not grow on galactinol, melibiose, raffinose and stachyose in contrast to WT (Fig. 2b). Therefore, MelB associated to its ABC transporter is the transport system responsible for the uptake and is necessary for the assimilation of these four molecules in pure culture.

MelB exhibits a high affinity for galactinol. Binding of galactinol, melibiose, raffinose and stachyose to the purified recombinant mature protein MelB was explored using tryptophan fluorescence spectroscopy (MelB possesses 16 tryptophans) and isothermal titration microcalorimetry (ITC). Intrinsic protein fluorescence titration experiments yielded apparent dissociation constant K_D values of 10 ± 1 nM and 72 ± 4 nM with galactinol and melibiose, respectively showing that MelB is very efficient for galactinol binding. Reducing the ligand size to a monosaccharide (galactose) or increasing it resulted in a substantial affinity reduction compared with galactinol: K_D values of 35-fold higher for the raffinose, and over 1000-fold higher for both galactose and stachyose, respectively (Table 1 and Supplementary Fig. S1). The K_D values were slightly higher using ITC than those determined by autofluorescence, but this increased K_D was consistent (Table 1 and Supplementary Fig. S1). Because MelB was not stable at high concentration during the time course of ITC experiment, we were not able to measure an interpretable signal for the stachyose binding. The ITC data confirmed the 1:1 binding stoichiometry for all ligands and revealed a high enthalpy of binding for galactinol and melibiose meaning that both ligands use the same binding mechanism mainly involving polar interactions. In contrast, the binding mode of raffinose was characterized by an unfavourable enthalpy

contribution and a strong entropy term indicating that hydrophobic interactions may play a predominant role and/or a displacement of water molecules occurs upon ligand binding. The galactose interaction adopts an intermediate behaviour with a high entropy term, accompanied by a weakly favorable enthalpy of binding suggesting that polar bonds are less important for galactose alone compared with a 2-units ligand, resulting in a lower enthalpy thus a weaker affinity. MelB is specific for α-(1,6)-galactosides (RFOs). Indeed, no interaction could be measured with glucose, sucrose, cellobiose, lactose and α-(1,6)-glucosides.

Thermal denaturation experiments revealed a contribution of more than 3°C for two ligands for protein stability (Supplementary Fig. S2). Indeed, adding galactinol or melibiose lead to a melting temperature (Tm) of over 46°C compared to the 43°C for the unliganded protein in agreement with the measured K_D values. Galactose or stachyose binding did not stabilize MelB while the raffinose binding produced a slight effect with a Tm of 45°C.

MelB is a PBP from Cluster C. The mature MelB expression plasmid was a synthetic gene lacking the first eighteen signal sequence residues that serve for localization to bacterial periplasm. The numbering used for the description of residues corresponds to the mature protein of 677 amino acids. Since MelB is the biggest PBP so far and shares low sequence identity (around 20%) compared to PBPs with known three-dimensional structures, we first solved the structure of seleniated MelB in complex with raffinose at 2 Å resolution by single-wavelength anomalous dispersion method. The asymmetric unit is composed of four similar MelB-raffinose complexes (average root mean square deviation (RMSD) value of 0.4 Å). By the molecular replacement method, we then solved the structure of MelB in complex with galactinol, melibiose, galactose and stachyose at 2.2 Å, 1.8 Å, 2.5 Å and 2.1 Å resolution, respectively (Table 2). The asymmetric unit of the galactinol and melibiose complexes also contains four very similar molecules with RMSD values between monomers ranging from 0.2 to 0.4 Å while that of the galactose and stachyose complexes possesses two identical molecules. Moreover, the five ligand-bound structures are very similar with an average RMSD value of 0.4 Å. They all adopt a closed conformation. MelB fold is monomeric composed of two lobes, each formed by a central β-sheet flanked by α-helices (Fig. 3a). The biggest lobe (lobe 1) consists of residues 8-354 and 619-678 and the smallest (lobe 2) comprises the residues 364-610. Two short segments (Fig. 3a) define the hinge region connecting the two lobes. MelB possesses a typical fold of cluster C within the PBP structural classification (12) as SSM-EBI (http://www.ebi.ac.uk/msd-srv/ssm) reports: RMSD between MelB and similar PBP structures binding oligopeptide are over 2.6 Å for 450 Cα atoms. Nonetheless, a detailed structural comparison is irrelevant because MelB presents a distinct ligand binding site.

Ligand binding site of MelB. All ligands are bound between the two closed lobes of MelB. The size and the volume of the ligand binding site constrain the conformation of bound RFOs. Indeed, raffinose and stachyose bind in a very compact form (Fig. 3b) and the addition of a galactosyl moiety at the non-reducing end of stachyose corresponding to verbascose will abolish its binding, because the pocket is not large enough to accommodate a pentasaccharide. All ligands are well defined in their electron density maps except the fructose moiety of the stachyose likely responsible for its low affinity (Figs 3c-h). They share a buried non-reducing end galactosyl unit wedged between two aromatic residues (Trp317 and Trp639) which superimposes very well with the bound galactose alone (Figs 3c-h). These galactoses at position 1 make ten similar protein contacts involving the main chain amino group of Gly111 and the side chains of Arg320, Asn333, Glu335, and Glu641 from lobe 1 and both side chains of Tyr487 and Arg533 from lobe 2. The O6 atom of this pyranose interacts with a conserved water molecule observed in each complexed structures (except in molecule B of MelB-galactose complex), which in turn makes hydrogen bonds with the amino group of Gly112 and the side chain of Asp114. In both structures of MelB in complex with galactose and stachyose, the galactose at position 1 does not interact with Asn333 but due to two hydrogen bonds with the side chain of Glu335, it conserves ten interactions with MelB. Modelling a glucosyl unit at the non-reducing end (position 1) creates steric hindrance between the equatorial C4-OH and the Trp639 indol explaining the specificity of MelB for a galactosyl unit at position 1 as shown by the affinity measurement.

In contrast to position 1, at position 2, the glucosyl moieties of melibiose and raffinose, the inositol moiety of galactinol and the galactose

moiety of stachyose do not superimpose and can shift up to 3.5 Å to allow, for example, the fructose or the sucrose accommodation of raffinose and stachyose in the ligand binding site, respectively (Figs 3b-c). A conformational change less than 1 Å for W110 and Tyr487 side chains is observed in order to accommodate a glucosyl unit at position 2 (Fig. 3c). More arrangements from amino acids of lobe 2 can occur to accommodate the glucosyl units at positions 3 and 4 (Fig. 3c). For example, Trp557 is pushed away by more than 1 Å compared with the other liganded structures in order to find a room for the fructose at position 4. All units at position 2 have in common the stacking onto the aromatic indol of Trp110, with the optimum one for the inositol due to the shorter link (one carbon shorter) between the two subunits of galactinol compared with melibiose and RFOs. The melibiose's glucose and the inositol share only one protein contact: an oxygen interacts with the NH of the Trp639 side chain (Figs 3e-f). The inositol makes three additional hydrogen bonds with Asn484, Tyr487 and Ser515 from lobe 2 while the rest of the oxygens of the melibiose's glucose interacts with the protein side chains *via* water molecules only. In contrast, the glucose moiety of raffinose and the galactose moiety of stachyose at position 2 make an additional H-bond compared with inositol involving the side chains of Asp519 (Figs 3g-h). The fructose at position 3 in raffinose interacts with the main chain of Arg533 from lobe 2 and the NH of the Trp639 indol from lobe 1 (Fig. 3g). In contrast, Arg532 side chain makes two H-bonds with the glucose moiety at position 3 in stachyose whereas only one is present between the fructose moiety at position 4 and the Trp639 side chain (Fig. 3h).

MelB is highly conserved among rhizobiales. Searching for MelB conservation in the bacterial kingdom (protein database at NCBI), and subsequent phylogenetic analysis revealed >310 PBPs above 65% sequence identity (Fig. 4). Galactinol, melibiose and raffinose binding signatures share 10 amino acids Trp110-Gly111-Trp317-Arg320-Asn333-Glu335-Tyr487-Arg533-Trp639-Glu641. Stachyose binding shares only nine of these latter because Asn333 does not interact with stachyose. Two additional residues (Asn484 and Ser515) are involved in galactinol, raffinose and stachyose binding compared to melibiose binding. One additional residue Asp519 belongs to the raffinose and stachyose signatures. A last additional residue Arg532 defines the stachyose binding signature composed of 13 residues in total. Members of the MelB subgroup (67 PBPs) display more than 90% identity sequence with the conserved binding signature. They all belong to *Rhizobium* and *Agrobacterium* genera. Outside the MelB-cluster, the signature slightly degenerates for galactinol and raffinose binding. Nonetheless, modeling indicates that their binding would not be affected. Remarkably, all these PBPs belong to soil and plant interacting genera.

Galactinol and melibiose are inducers of *mel* operon genes. We constructed the C58 pOT1e-P_{mel} reporter fusion strain in order to study *in cellulo* gene expression of *mel* operon in the presence of commercial compounds. Compared to succinate, slights but significant inductions were observed with raffinose, galactose and stachyose (2, 1.6 and 1.25 fold change values respectively; Fig. 5a). In contrast, galactinol and melibiose are efficient inducers with 4.8 and 6.5 fold change values respectively.

***mel* operon genes are expressed in early plant colonization.** At two early stages of plant colonization, *in planta* expression of *mel* operon has been studied in the WT strain harbouring the pOT1eM-P_{mel} plasmid reporter fusion (*m-cherry* constitutive expression and *e-gfp* inducible expression). 48h after seed imbibition and inoculation, most bacteria in contact with the radicle cells expressed *mel* operon, as shown by the yellow cells in Figs 5b-c. 14 days after seed imbibition and inoculation, among bacterial cells present on plant roots (red and yellow cells), some of them were still expressing RFOs uptake and degradation genes (yellow cells in Fig. 5d). Thus, *mel* operon was more expressed at the beginning of plant colonization.

The PBP MelB confers a competitive advantage in colonizing tomato rhizosphere. The colonization of plant rhizosphere by *A. fabrum* C58 WT and C58Δ*melB* mutant was evaluated at 2 days post-inoculation (dpi) and 14 dpi (Fig. 6). When tomato seeds were inoculated with each strain individually, the bacterial colonization level did not significantly differ at 2 dpi (Mann-Whitney *P-value* of 0.09) whereas at 14 dpi, this was slightly higher for the WT strain (Mann-Whitney P-value < 2.2e-16e; Fig. 6a). When *A. fabrum* C58 WT and C58Δ*melB* mutant were co-inoculated, a slight and a drastic reduced fitness was observed for the C58Δ*melB* mutant at 2 and 14 dpi, respectively (Fig. 6b), revealing a

selective advantage conferred by galactinol/melibiose/RFOs exploitation under a competitive challenge.

DISCUSSION

This work reveals the molecular and ecological roles, and structural basis of the PBP MelB, encoded by the linear chromosome of *A. fabrum* C58.

At the beginning of the study, we made the straightforward assumption that MelB was behaving like its homologous PBP AgpA from *E. meliloti* described as an α-galactosides transporter (13). Our gene expression analyses and growth assays experiments showed that similarly to what has been reported for expression of *agp* operon genes in *E. meliloti*, α-galactosides induce expression of *mel* operon genes in *A. fabrum*, and are used as carbon sources after being imported by MelB. Indeed, in contrast to the WT strain, a MelB defective mutant is unable to grow on α-galactosides. Moreover, using two different biophysical methods, we demonstrated that MelB can bind melibiose, raffinose and stachyose. Due to the small volume cavity of the ligand binding, stachyose displays a weak affinity for MelB (micromolar range) compared with melibiose and raffinose (nanomolar range). The accommodation of stachyose requires drastic conformational constraints on the ligand when bound to the protein. Indeed, only small local rearrangements of few protein side chains (W110 and W557) forming the binding site can occur. With an affinity in the micromolar range, MelB also binds galactose, which is the sugar common to all α-galactosides present at the non-reducing end. Nonetheless, the low affinity of MelB for galactose prevents galactose from competing with melibiose and raffinose. From our results, MelB can appear as an alternative galactose transporter suspected by Kemner et al. (23), which allowed a *chvE-gguABC* defective mutant to grow on galactose (23, 24). Conversely, the presence of the ChvE-GguABC sugar transporter can explain why *melB* defective mutant was still able to grow on galactose.

An unexpected outcome of our study was that galactinol, which is the precursor of α-galactosides production in plant, was uptaken into agrobacteria *via* the MelB-mediated transport system. Moreover, MelB displays a preference for galactinol with high affinity (nanomolar range) indicating that this molecule must be efficiently imported into *A. fabrum*, in line with the gene expression results. Remarkably, MelB recognizes similarly the non-reducing end galactose common to all tested α-galactosides and galactinol. Overall, using genetic, structural and affinity data, this work demonstrates that the MelB-mediated transport system contributes to the import of α-galactosides with a strong preference for a 2 units-ligand (melibiose) and mainly contributes to that of galactinol. To our knowledge, this is the first description of a bacterial PBP allowing galactinol import.

The imported sugars are used to sustain bacterial growth. Galactinol and α-galactosides rich-environments would facilitate the settlement of bacteria capable to assimilate these plant compounds efficiently. From *in planta* competition assays on tomato between the *A. fabrum* WT and *melB* defective mutant, we showed that MelB confers a marked selective advantage in colonizing tomato rhizosphere, and since in early time. This observation correlates with the presence of melibiose and raffinose in the plant rhizosphere, as they are highly abundant in the seeds (25) and known to be released during seed germination (14). Hence, the competitive advantage of the WT in the tomato rhizosphere could be due to a trophic advantage of the strain during seed germination. A germinating seed can indeed be considered as a new environment to be colonized. The community composition of the mature plant is influenced by historical contingency (timing and order of arrival) of the seed community members and their ability to efficiently settle in that environment (26), as the first establishing species are known to affect the ability of potential immigrants to establish. This is called the priority effect (27). Thus, the ability of bacteria to compete and settle in germinating seed environment by growing on galactinol or α-galactosides released at this time could have long effect on their ability to persist and colonize plant rhizosphere. This is consistent with our findings that at 14 days post inoculation (dpi), the competitive advantage of the WT strain is even higher than the one measured at 2 dpi.

Besides the trophic advantage linked to the *mel* operon, this operon could be associated to another aspect of bacterial plant interactions, linked to plant defenses signaling and protection against pathogens. Indeed galactinol is a plant compound involved in plant defense (9–11). For example, *Pseudomonas chlororaphis* O6-mediated induced systemic resistance was shown associated with an elevation of galactinol content within plants, which conferred disease resistance against pathogen attack (9). The disease resistance was

associated with induction of the expression of a set of pathogen-responsive genes (9, 10). Moreover, in Arabidopsis, deletion of enzymes that decreases the galactinol and/or raffinose content has been shown to increase plant resistance against the phytopathogenic nematode *Heterodera schachtii* (11). Similarly, *Agrobacterium mel*-mediated activity could modify the level of plant galactinol and/or raffinose, which could either drive bacterial recognition by the plant, or reduce plant defense signaling through the fall of galactinol content. *Agrobacterium* is known to be able to bypass and overcome plant defenses (28). It would thus be of interest to study the involvement of the *mel* operon in that situation.

In this study, we defined the galactinol/melibiose/raffinose binding signature and found out that this is strictly conserved in MelB homologues in *Agrobacterium* and *Rhizobium*, which share a high sequence identity over 90% with MelB. Moreover, phylogenetic and structural data showed that this wide occurrence is extended among *Rhizobiaceae*, all plant interacting genera (*Mesorhizobium*, *Allorhizobium*, *Ensifer*, *Martelella*, *Pleomorphomonas*, *Kaistia*, and *Devosia*). Therefore, whatever advantage it gives, it is tempting to speculate that galactinol/melibiose (and to a lesser extent raffinose) may be associated with a selective pressure towards the acquisition of binding, transport and degradation functions in micro-organisms, making the PBP MelB, as a major trait in the first step of tomato colonization and likely of other plant species.

EXPERIMENTAL PROCEDURES

Bacterial culture conditions. Bacteria and plasmids used in this study are shown in Supplementary Table S1. *Escherichia coli* strains were grown at 37°C in LB media supplemented when it was necessary with appropriate antibiotics (tetracycline 10 µg/mL, gentamicin 15 µg/mL, ampicillin 100 µg/mL). *A. fabrum* C58 strain and its derivatives were cultivated at 28°C in YPG (Yeast extract: 5 g per liter, Peptone: 5 g per liter, Glucose: 10 g per liter and pH adjusted to 7.2) rich medium supplemented when required with neomycine (25µg/mL), kanamycine (25µg/mL) and/or gentamycin (20µg/mL). In growth assays, AT minimal medium supplemented with 10 mM ammonium sulfate and 10 mM of carbon sources was used. 200 µL were inoculated in Bioscreen honeycomb 100-well sterile plates and incubated in a Bioscreen C Reader (Labsystems, Helsinki, Finland) at 28°C during 5 days. Cells growth was measured every 20 min. Analyses were performed in five technical replicates and in three biological replicates.

Construction of *melB* defective mutant in *A. fabrum* C58 and transcriptional fusion. The *A. fabrum* C58Δ*melB* defective mutant was constructed as previously described (29) without marker exchange. Briefly, the recombinant region containing the upstream and downstream region flanking the *melB* gene (amplified by PCR using primers listed in the Supplementary Table S2) was inserted into pJQ200sk vector (30) leading to a non-polar mutant. The resulting plasmid was introduced into *A. fabrum* C58 by electroporation. Bacteria was spread on YPG medium plates containing gentamicin (20µg/mL) for the first selection and gentamicin-resistant colonies were spread on YPG plates supplemented with 5% of sucrose for the second selection. The deletion of *melB* was verified by sequencing (GenoScreen, Lille, France).

The C58 pOT1e-P_{mel} transcriptional reporter fusion strain was obtained as follows: the promoter region of *atu4660-atu4665* genes named P_{mel} was PCR amplified (using primer listed in the Supplementary Table S2) and the PCR fragment obtained was ligated into ClaI-SalI digested vector pOT1e. pOT1eM-P_{mel} plasmid was obtained by cloning P_{mel} into SpeI digested-pOT1eM vector as previously described (31). Transcriptional reporter constructions were introduced into *A. fabrum* by electroporation.

Cloning, expression and purification of mature MelB. The mature MelB expression plasmid was chemically synthesized using codon optimization for the expression in *E. coli* and inserted into pET-9a plasmid using NdeI and BamHI restriction enzyme (Genscript, Piscataway, NJ). *E. coli* BL21 competent cells transformed with pET9a-MelB were grown in LB media at 37°C until OD_{600} of 0.6. 0.5 mM of isopropyl β-D-1-thiogalactopyranoside (IPTG) was added to the culture for overnight expression at 20°C. The cells were pelleted by centrifugation at 4000 g for 15 min at 4°C, resuspended in 50 mM Tris-HCl pH 8, 300 mM NaCl and 20 mM imidazole and disrupted by sonication. After centrifugation at 25000 g for 30 minutes, the filtered supernatant is injected on a nickel affinity column (HiTrap 5 ml, GE Healthcare). After a washing step of 6% of 50 mM Tris-HCl pH 8, 300 mM NaCl and 300 mM

imidazole (Buffer B), the protein is eluted with Buffer B and injected on a gel filtration Superdex 200 26/60 (GE Healthcare) using 50 mM Tris-HCl pH 8 and 150 mM NaCl. The protein fractions are pooled, concentrated at 10.7 mg/mL and stored at -80°C.

Expression and purification of mature seleniated MelB. The *E. coli* BL21 cell transformed with the plasmid pET9a-MelB were grown overnight at 28°C in M9 media supplemented with 0.4% Glucose, 2 mM $MgSO_4$, 1 µM $CaCl_2$, 100 mg/L of lysine, threonine, and phenylalanine, 50 mg/L of leucine, valine, isoleucine and methionine. The pelleted cells were resuspended in fresh M9 media (same as above) with 100 mg/L of selenomethionine instead of methionine for 1 h at 37°C before inducing the expression with 0.5 mM IPTG overnight at 20°C. The cells were centrifuged at 4000 g for 15 min at 4°C. The purification protocol was the same as described above.

Crystallization and data collection of MelB. Crystallization conditions for seleniated MelB in the presence of 2 mM raffinose were screened using Qiagen kits (Valencia, CA, USA) with a Cartesian nanodrop robot (Genomic solutions). The crystals were manually reproduced in hanging drops experiments by mixing equal volumes of protein solution and the precipitant solution 25% PEG 4000, 0.2 M NaCl, 0.1 M Mes pH 6.5 and 0.2 M $CaCl_2$. For the four other complexes, a similar condition without $CaCl_2$ and 0.6 M NaCl was used. Crystals were transferred to a cryoprotectant solution (mother liquor supplemented with 25% PEG 400) and flash-frozen in liquid nitrogen. X-ray diffraction data sets were collected at 100 K on the Proxima 1 or 2 beamlines (SOLEIL synchrotron, Saint-Aubin, France). Data processing was performed using the XDS package (32) (Table 2).

Structure determination and refinement of MelB. The crystal structure of the MelB-raffinose complex was determined by SAD method from selenomethionine-labelled protein and refined at 2 Å resolution. Solvent content analysis using CCP4 (Collaborative Computational Project, Number 4) indicated the presence of four monomers in the asymmetric unit. The positions of 12 over 15 selenium atoms per monomer were found using SHELX suite program (33) The phases were calculated using PHASER (34) and density modification was performed by PARROT (CCP4 suite). An iterative process of manual building in COOT combined with phase calculation where a partial model was used as input, allowed the modelling of the complete polypeptide chain. The structures of all other liganded MelB were solved using the SeMet-MelB monomer as a search model. Refinement of each structure was performed with BUSTER-2.10 (34), NCS restraints and TLS group. Because of the strong anisotropy of the crystals of MelB-stachyose, the DEBYE and STARANISO programs developed by Global phasing Ltd were applied to the data scaled with AIMLESS using the STARANISO server (http://staraniso.globalphasing.or/). These programs perform an anisotropic cut-off of merge intensity data on the basis of an analysis of local I/s(I), compute Bayesian estimates of structures amplitudes, taking into account their anisotropic fall-off, and apply an anisotropic correction to the data. The corrected anisotropic amplitudes were used for further refinement of the MelB-stachyose structure with BUSTER-2.10. Inspection of the density maps and manual rebuilding were performed using COOT (35). The three dimensional models of stachyose and galactinol was generated with the ProDRG webserver (36) while those of melibiose and raffinose were found in the protein data bank. Refinement details of each structure are shown in Table 2. Molecular graphics images were generated using PyMOL (http://www.pymol.org).

Fluorescence titration measurements of MelB. Each ligand bound to MelB was monitored by autofluorescence by excitating the protein at a wavelength of 295 nm and monitoring the quenching of fluorescence emission of tryptophans at 335 nm. All experiments were performed at 22°C in 96 wells plates (1/2 Area Plate-96F, Perkin Elmer) using Tecan Infinite M1000 (Tecan, Männedorf, Switzerland) in 25 mM Tris-HCl pH 8.0 and 150 mM NaCl with a fixed amount of proteins (1 µM) and increasing concentrations of ligand. Each ligand has no emission signal at 335 nm. The data were analysed using Origin® 7 software and fitted to the equation $f=\Delta Fluorescence_{max}*abs(x)/(K_D+abs(x))$.

Isothermal titration microcalorimetry measurements of MelB. Isothermal titration microcalorimetry experiments were performed with an ITC200 isothermal titration calorimeter from MicroCal (GE Healthcare). The experiments were carried out at 20°C. Protein concentration in the microcalorimeter cell (0.2 mL) varied from 10

to 300 µM. 19 injections of 2 µl of ligand solution (raffinose, stachyose, melibiose, galactose and galactinol) concentration from 0.1 to 2.8 mM were performed at intervals of 180 s while stirring at 500 rpm. The experimental data were fitted to theoretical titration curves with software supplied by MicroCal (ORIGIN®). This software uses the relationship between the heat generated by each injection and ΔH (enthalpy change in Kcal.Mol^{-1}), Ka (the association binding constant in M^{-1}), n (the number of binding sites), total protein concentration and free and total ligand concentrations (37).

Differential scanning calorimetry. Thermal stability of the WT and liganded MelB (13 µM and 50 µM for protein and ligand, respectively) was studied by differential scanning calorimetry (DSC) on a MicroCal model VP-DSC in a standard buffer. Each measurement was preceded by a baseline scan with the standard buffer. All solutions were degassed just before loading into the calorimeter. Scans were performed at 1K.min-1 between 20 and 90°C. The heat capacity of the buffer was subtracted from that of the protein sample before analysis. Thermodynamic parameters were determined by fitting the data to the following equation:

$$\Delta C_p(T) = \frac{K_d(T)\,\Delta H_{cal}\,\Delta H_{vH}}{[1+K_d(T)]^2\,RT^2}$$

where Kd is the equilibrium constant for a two-state process, ΔHvh is the enthalpy calculated on the basis of a two-state process and ΔHcal is the measured enthalpy.

Phylogenetic analysis. Sequences were analysed using BlastP from NCBI (https://blast.ncbi.nlm.nih.gov/) and MicrosScope (https://www.genoscope.cns.fr/). Alignments of MelB and related sequences were conducted using ClustalW software. Relationship tree was build using Mega software, version 7. The bootstrap consensus tree inferred from 1000 replicates was taken to represent the evolutionary history of the taxa analysed. The evolutionary distances were computed using the Poisson correction method and are in units of the number of amino acid substitutions per site.

Measurement of *mel* operon gene expression. Expression of *mel* operon genes was measured in the C58 pOT1e-P$_{mel}$ strain. Quantification of fluorescence was carried out in a microplate filled with 200 µl of AT medium, supplemented with different carbon sources at a final concentration of 10 mM. Microplate wells were inoculated with overnight cultures to obtain an OD_{600} of 0.2. A TECAN apparatus (Tecan Spark™ 15M, Männedorf, Switzerland) was used to read microplates after 24 hours of incubation at 28°C. The following parameters were used: absorbance at 600 nm, fluorescence excitation at 488 nm, and emission at 510 nm. Results were normalized by the OD_{600} and fold change values were obtained by dividing the fluorescence by the corresponding value obtained from the empty pOT1e vector. The fluorescence level comparison was carried out using the Tukey test (*P-value*=0.05) and computed with the "vegan" package in the R v3.1.3 statistical software environment (R Core Team, 2014).

Plant inoculation. For bacterial colonization, competition assays and confocal observation studies, tomato seeds (*Solanum lycopersicum* "Marmande") were sterilized as described (38). Seeds were plated on 0.8% of agar plant cell culture supplemented with 1.5 g/L of the Plant-Prod 15-15-30 High K nutrient solution (Master Plant-Prod Inc., Brampton, Canada). They were inoculated with 10 µl of overnight culture (10^6 CFU/ml) of a single strain (*A. fabrum* C58 pTiatu6148:Km derivative of the WT strain (39) or C58Δ*melB* mutant), or with a mixture of both at 1:1 ratio (competition). Petri dishes were placed two days in the dark and then in a climatic chamber at 24°C with 18/8 h for light/dark and 65% of humidity. To determine bacterial colonization level, roots were grinded at 2 and 14 dpi. Serial dilutions of crushed roots were plated on the YPG medium and colonies were counted after 2 days of incubation at 28°C. Significant difference in the population level resulting from five plants per strain, with enumeration of three petri dishes for each plant was evaluated with Mann-Whitney test (*P-value*=0.05) performed with the R v3.1.3 statistical software environment (https://www.r-project.org).

In competition experiments, the colonized bacteria were non-selectively recovered at 2 dpi and 14 dpi. To that end, crushed roots were first plated with a spiral plater (EasySpiral®, Interscience, Saint- Nom-la-Bretèche, France) on YPG media without antibiotics to enable a biologically unbiased recovery of both C58 pTiatu6148:Km WT strain and C58Δ*melB* mutant (kanamycine sensitive). Two hundred individual colonies where then plated in YPG medium with kanamycin/neomycin in order to determine the relative proportions of C58 pTi*atu6148*:Km and C58Δ*melB* mutant strains (output ratio). The

determination of the initial strains ratio of the inoculum was realized using the same protocol. The experimental assays were performed with ten independent assays and repeated four times. The proportions of WT strains between the initial strain ratio and *in planta* output ratios were compared with the test of equal or given proportions (*P-value*= 0.05).

Confocal microscopy analyses. Visualisation of reporter bacterial cells harbouring pOT1eM-P*mel* on tomato radicles and roots was performed using a confocal laser scanning microscope (LSM 800 Meta Confocal Microscope; Zeiss, Oberkochen, Germany). In the reporter strain, M-Cherry (red color) is constitutively expressed and eGFP (green color) is expressed under P*mel* control. The red color indicates the bacteria presence (red cells) while eGFP reports the induction of *Pmel* shown as yellow-green cells. At 2 and 14 dpi, tomato radicles and roots were mounted between a slide and a coverslip in a commercial mounting fluid (Aqua Poly/Mount; Polysciences, Inc., Warrington, PA.). The eGFP and the M-cherry were excited with argon laser at 488 nm and 584 nm, respectively, and fluorescence was captured at 528 nm and 607 nm. Analyses of images (5 plants per condition) were performed thanks to LSM 800 software (Zeiss, Oberkochen, Germany).

Acknowledgements: TM, AV, SM, and CL was supported by CNRS (Mission pour l'interdisciplinarité, Agromics 2014-2016). TM received a doctoral grant from the French Ministère de l'Education Nationale, de l'Enseignement Supérieur et de la Recherche. This work has benefited from the I2BC crystallization and microcalorimetry platforms supported by FRISBI ANR-10-INSB-05-01 as well as from the "Centre Technologique des Microstructures" and the "Serre et chambres climatiques" platforms, supported by the FR BioEnviS Research Federation. We acknowledge SOLEIL for provision of synchrotron radiation facilities (proposals ID 20130869, 20140774 and 20160782) in using Proxima beamlines. We thank Andrew Saurin for critical reading of the manuscript.

The atomic coordinates and structure factors have been deposited at the Protein Data Bank (PDB) under accession codes 6EPY (seleniated MelB with raffinose), 6EQ1 (MelB with stachyose), 6EQ8 (MelB with galactinol), 6EPZ (MelB with melibiose) and 6EQ0 (MelB with galactose).

Conflict of interest: The authors declare that they have no conflicts of interest with the contents of this article.

Author Contributions: TM, LV and CL performed all the microbiology work. AV and SM performed all the crystallography work. AV performed the fluorescence assays. AV and MAN performed the microcalorimetry experiments. AV, TM, CL and SM performed the phylogenetic analysis. SM and CL wrote the manuscript. All the authors discussed the results and contributed to the writing of the manuscript.

$CC_{1/2}$ = percentage of correlation between intensities from random half-dataset (40).

FIGURE LEGENDS

FIGURE 1. RFOs synthesis (a) and degradation (b). Reactions for synthesis are represented with black arrows while those for degradation in grey arrows. The first step of RFOs biosynthesis starts with the formation of galactinol from UDP-galactose and inositol catalyzed by the plant enzyme galactinol synthase. Raffinose, stachyose and verbascose are synthesized from sucrose by the subsequent addition of activated galactose moieties donated by galactinol using plant raffinose and stachyose synthases and galactan:galactan galactosyltransferase (GGT), respectively. Cleavage of raffinose by an α-galactosidase leads to the formation of either melibiose and fructose or sucrose and galactose. For RFOs of higher degree of polymerization (DP), an α-galactosidase activity results in RFOs of lower DP and galactose.

FIGURE 2. The *mel* operon structure and MelB involvement in galactinol, melibiose and RFOs consumption. (a) *atu4660-atu4665* genes belong to the same transcription unit (operon prediction by Westover *et al*. 2005 (22) that we called the *mel* operon). The *mel* promoter P_{mel} indicates the gene transcription direction. Both *atu4660* and *atu4665* genes are annotated as two α-galactosidases, *atu4661* as the Periplasmic Binding Protein MelB and *atu4662-atu4664* genes as the associated ABC transporter. Comparison between the *mel* operon genes and their homologues in *Ensifer meliloti* 1021 (13, 14). The percentages of sequence identity between each homologous protein are indicated, for example, the PBPs AgpA and MelB share 73% sequence identity (b**)** 2.5 days growth (OD at 600nm) of *A. fabrum* C58 WT strain (in white) and the C58Δ*melB* mutant (in black) in AT minimal medium supplemented with different carbon sources. Asterisks indicated significant differences (Mann-Whitney *P-value*=0.05).

FIGURE 3. Ribbon representation of MelB structures and ligand-binding site (a) Raffinose in magenta is located in the cleft between the lobes 1 and 2 shown in slate and in pink, respectively, and the hinge region is in red. (b) Superposition of the bound galactose, melibiose, galactinol, raffinose and stachyose shown in green, yellow, orange, magenta, blue sticks, respectively, in the binding site of MelB, (c) Same figure as in b showing the stacking between ligands and tryptophan (W639, W317 and W110). Except W639 and W317, all the other labelled amino acids mainly from lobe 2 can move up to 1 Å upon ligand binding. (d) galactose, (e) melibiose, (f) galactinol, (g) raffinose and (h) stachyose bound to the binding site of MelB are shown in the same code colour as in b. Hydrogen bonds between MelB and each ligand are shown as dashed lines in black (distances are up to 3.2 Å). A water molecule forming a hydrogen bond with each ligand is shown as a red circle. Each ligand is shown in its annealing Fo-Fc omit map contoured at 4σ.

FIGURE 4. MelB phylogeny and binding signature**.** For each protein clade, the residues, which are identical to (black) and different from (red) those involved in the galactinol/melibiose/raffinose binding of *A. fabrum* C58 MelB are indicated. Number in bracket represents the number of MelB-relative PBPs per clade.

FIGURE 5. Expression of *mel* operon genes *in cellulo* and in tomato radicle and root. (a) Comparison of *mel* operon gene expression in AT minimal medium supplemented with different carbon sources. Letters above histograms indicate significant different fold change values (Tukey test - *P-value*=0.05). (b, c, and d) Bacterial *mel* operon gene expression at two early stages of plant growth. Gene expression was monitored using the pOT1eM-P_{mel} transcriptional reporter fusion by confocal microscopy at 2 days (b and c) and 14 days (d) post-inoculation (dpi), corresponding to radicle emergence and root elongation stages, respectively. Representative pictures from five plants per stages are shown. Red fluorescence from M-cherry indicates the presence of bacteria, while yellow fluorescence shows bacteria that were both active and able to express P_{mel}-*egfp*. Plant auto fluorescence, represented in green allows distinguishing different types of plant cells: small compact cells from the radicle and elongated cells from the growing root. The scale is represented in white. Most cells expressed P_{mel}-*egfp* at 2dpi, whereas at 14 dpi, few cells only expressed the transcriptional fusion.

FIGURE 6. MelB confers a competitive advantage in tomato roots. (a) *A. fabrum* bacterial concentration (CFU/mg dry roots) in tomato roots (at 2 and 14 dpi) infected with either *A. fabrum* C58 WT or C58Δ*melB* mutant. (b) Proportion of *A. fabrum* genotypes (%) in inoculum and tomato root at 2

and 14 dpi infected with a mixture (1:1 ratio) of *A. fabrum* C58 WT and C58Δ*melB* mutant. Asterisks indicated significant differences (Mann-Whitney test).
